PROCEDURES FOR LATER STAGE PROCESSING OF SINGLE-REGION INPUT- OUTPUT DATA FOR SALTER

This working paper describes some of the later stage processing procedures for the single-region input-output tables of the SALTER database.

1 Introduction

SALTER is a multi-region multi-sector model of the world economy first documented in Jomini *et al.* 1991. It is designed as an instrument of economic policy analysis, in particular, for analysing trade and industry policies in an international context.

The SALTER database contains a variety of data, with multi-region input-output data comprising the bulk of it. The database is assembled from several smaller files, including a set of single-region input-output tables and an international trade database.

Preparing the SALTER database is a three-stage process involving data collection, adjustment, and assembly. In the first stage, we collect statistics from various sources, arrange them into standard file structures, and transform them into standard sectoral classifications. In the second stage, we adjust the data to eliminate inconsistencies between sources. In the third stage, we assemble the adjusted data to form the SALTER multi-region database.

This paper covers some of the procedures used in processing the single-region input-output tables in the second stage of database preparation. We call this second stage the *later stage processing* of the single-region input-output tables. The expression 'later stage processing' distinguishes the adjustment procedures in the second stage of database preparation from the initial construction or *early stage processing* in the first stage.

The main purpose of the later stage processing of the single-region input-output tables is to adjust the tables to other data used in the SALTER database. These other data include international trade data (Hambley 1993, Hanslow 1993),

assistance data (Gotch 1993) and macroeconomic data (Brown, Strzelecki and Watts forthcoming). The bulk of this work is done by FIT, an input-output update facility documented in James and McDougall (1993). However, some preprocessing procedures need to be undertaken before FIT can be used. This paper documents the necessary preprocessing procedures.

2 Preprocessing the input-output tables to eliminate zero trade flows: motivation

One of the purposes of the FIT program is to adjust the trade values in a single region input-output table to agree with independently derived international trade data. It achieves this, along with other objectives, using input-output modelling techniques. Indeed, the FIT program is nothing more than a kind of single-region input-output model implemented using GEMPACK (Codsi and Pearson, 1988, Pearson and Codsi 1991). Any one of the single-region input-output tables can act as the model's database. The required adjustments to the input-output table can be represented as shocks to the model. The revised input-output table can then be generated by a FIT simulation as an updated database. But before FIT can be used, zero trade flows need to be eliminated from a FIT database.

There are two reasons for eliminating zero trade flows before running FIT. One is that FIT, like most GEMPACK-based models, is expressed in percentage change form. With the percentage change formulation, all zero values in the original database remain zero in the updated database, no matter what shocks are applied to the model. So for any commodity for which the international trade database specifies non-zero trade values, we must have non-zero trade values in the FIT input database.

This reason for eliminating zero trade flows is valid but not decisive: an alternative solution is available, namely rewriting FIT to avoid the percentage change formulation in trade flows. But the second reason is decisive. It relates to the import sales disposition in the updated database.

If the target value from the trade database for aggregate imports of a commodity is positive, then the updated input-output table must contain a complete import sales disposition for that commodity. This sales disposition will be based on the

sales disposition in the initial database. But if aggregate imports of the commodity in the initial database are zero, then the initial table contains no information about the sales disposition, and a revised sales disposition cannot be constructed.

Accordingly, before inputting the single-region input-output tables into the FIT update simulations, we pre-process them to eliminate zero flows for exports and imports. For commodities that originally had zero import flows, we want the new import sales dispositions to be sensible. Finally, we want the new positive trade flows to be small, to minimise distortions to the original input-output data.

3 Preprocessing the input-output tables to eliminate zero trade flows: approach

We begin with the question, how to construct sensible import sales dispositions in preprocessing the single-region input-output tables.

The sales disposition of an imported commodity in a region depends on two main factors: the intensity with which it is used in each economic activity, and the profile of economic activity in the region. If the database for one region originally shows zero usage in all activities, we look to the other regions in the SALTER model to see which activities typically use the commodity most intensively. A sensible sales disposition takes account both of these typical usage intensities, and of the profile of economic activity in the region.

More precisely, we can divide the input-output table in each region into three elements: the *indirect tax structure*, the *input-output structure*, and the *final demand profile*. The indirect tax structure consists of commodity tax rates and production tax rates. The input-output structure consists of various expenditure share coefficients. The final demand profile shows aggregate expenditure in each final demand category (for SALTER, household consumption, government consumption, investment, and exports).

The input-output structure in turn divides into two levels. The upper level shows the shares of each commodity in each industry's total costs, and in aggregate expenditure for each final demand category (*commodity shares*). The lower level shows the shares of domestic products and imports in expenditure on each

commodity for each demand category (domestic product shares and *import shares*).

Note that we calculate the commodity shares as shares in total costs *excluding* production tax. This is because we include the production tax rate in the indirect tax structure rather than the input-output structure.

In preprocessing the single-region input-output tables we revise the input-output structure while preserving the indirect tax structure and the final demand profile. To achieve positive import usage, not only the import but also the commodity shares must be positive. To ensure this we revise both the lower and the upper levels of the input-output structure. At the same time we keep changes at both levels small, to minimise distortions to the original input-output data.

In revising the input-output structure for each region in the model, we turn to the other regions for guidance. More precisely, we refer to a *representative* input-output table, constructed by summing the input-output tables over all SALTER regions. To ensure that each region is suitably weighted in the representative table, we first scale all the individual region tables to a common unit of account (millions of US dollars) and a common reference year (1988).

To revise the input-output structure for each region, we calculate new input-output coefficients as weighted averages of coefficients from the original input-output table and the representative table. The weights are arbitrary. We choose a large positive weight for the original individual-region table, and a small positive weight for the representative table.

By assigning a much greater weight to the original individual-region table than to the representative table, we ensure that changes to the input-output structure are small. By assigning a positive weight to the representative table, we ensure that each commodity has positive import usage in each of the revised individual-region tables, provided that it had positive import usage in at least one of the original tables. Likewise we ensure that each commodity has positive export sales in all the revised tables, provided that it had positive exports in at least one of the original tables.

In the original input-output tables for SALTER, (Hambley 1993, Brown *et al.* forthcoming) every commodity in the model has positive import usage in at least

one region, and positive export sales from at least one region. Thus this approach accomplishes the objectives of the preprocessing.

4 Programs and file structures

Several utility programs were developed to undertake the preprocessing and processing.

- SCALE rescales a single-region input-output table.
- SUMDB sums over a collection of input-output tables to generate a new input-output table.
- EXTRACT extracts input-output coefficients from an input-output table.
- AVERAGE calculates weighted averages over two files of input-output coefficients to generate a new coefficients file.
- PROJECT extracts the final demand profile from an input-output table and combines it with independent data for input-output coefficients to generate a new input-output table.
- FIT adjusts an input-output table in accordance with user-supplied information about international trade, domestic final demand, etc.

All these utilities are FORTRAN programs. Some are written by hand, others using the GEMPACK code-writing program TABLO. The TABLO-written FORTRAN programs include both data handling utilities and implementations of economic models. The former merely calculate and write coefficients, while the latter can set up and solve systems of equations and update databases.

Each utility takes user-supplied instructions and one or more data files as input, and writes a data file as output. The user input may be provided either interactively or as a stored input file. All data files are in the header array format developed for GEMPACK data files (Mikkelsen and Pearson 1986).

This section describes these programs, and the files that they handle. Source code listings for the programs are given in the appendixes. The required user input for the programs is described in Brown *et al.* (forthcoming).

File structures

Three kinds of data files are handled by the utility programs: single-region input-output tables, single-region input-output coefficients files, and a region-generic data file. All these files conform to the GEMPACK header array format.

The single-region input-output tables are involved in all three stages of database construction (data collection, adjustment, and assembly). In developing the later stage processing procedure the structure of these files was taken as given; it is shown here for ease of reference. The input-output coefficients files and the region-generic data file are used only in revising the single-region input-output tables in the second stage.

The single-region input-output coefficients file is designed to record the input-output structure of a single-region input-output table. In the input-output structure we include commodity and primary factor shares in each industry's total costs, commodity shares in aggregate expenditure on each category of final demand, and domestic product and import shares in expenditure on each commodity in each demand category. To keep the input-output structure separate from the indirect tax structure, we calculate the industry cost shares as shares in total costs excluding production tax.

The region-generic data file contains some pieces of information which are common to all regions. These include the dimensions of the model, and parameters settings for use with programs AVERAGE and FIT.

Tables 1 to 3 list the headers for each kind of file. Table 4 lists the contents of the region-generic data file, as set up for SALTER.

In Table 4, note that the the number of sectors specified in the region-generic data file must agree with the actual number of sectors in the single-region input-output tables. The weight parameters used with AVERAGE and FIT can be set arbitrarily. The weights need not sum to one; only the relative weights matter.

Programs

For each program, we list the input and output data files, and describe the required user input (other than file names for input and output data files, which are in all cases user-supplied). We then outline the operation of the program.

For an account of how we combine the programs to perform the later stage processing, see Section 5.

SCALE

SCALE is a TABLO-written FORTRAN program, designed to rescale a single-region input-output table.

SCALE is a data handling routine. It reads a single-region input-output table and the region-generic data file, and writes a new input-output table. The user supplies a target value for gross domestic product (gdp) for the new input-output table, denominated in the required unit of account (millions of US dollars) and for the required reference year (1988). We use SCALE to ensure that each region is suitably weighted in the representative input-output table.

SCALE calculates gdp from the initial input-output table, then the ratio of target to initial gdp. It then multiplies all arrays in the initial input-output table by this ratio, generating a new input-output table in which gdp assumes the target value.

SUMDB

SUMDB is a hand-written FORTRAN program, designed to sum a collection of input-output tables.

SUMDB reads a collection of input-output tables, and writes a new input-output table. The number of tables to be read is specified by the user. We use SUMDB to generate the representative input-output table.

Each element in each array in the new input-output table is calculated as the sum of the corresponding elements in the old tables.

In its current implementation, SUMDB can sum up to fourteen input-output tables at a time. Groups of fifteen or more tables can be summed using multiple applications of SUMDB.

EXTRACT

EXTRACT is a TABLO-written FORTRAN program, designed to extract the input-output structure from an input-output table.

EXTRACT is a data handling routine. It reads an input-output table and the region-generic data file. It writes an input-output coefficients file. We use EXTRACT to extract the input-output structure from the initial individual-region input-output tables and from the representative table.

For regions whose input-output tables containing some zero flows, some of the share coefficients may be undefined. This occurs when the divisor in the share formula is equal to zero. In such cases, EXTRACT uses the TABLO zerodivide default facility to assign the share coefficient a value of zero.

AVERAGE

AVERAGE is a TABLO-written FORTRAN program, designed to calculate averages of input-output coefficients across two input-output coefficients files.

AVERAGE is a data handling routine. It reads two input-output coefficients files and the region-generic data file. It writes an input-output coefficients file. We use AVERAGE to generate revised individual-region input-output structures consistent with non-zero trade flows.

Each element in each array of the new input-output coefficients file is calculated as a weighted average of the corresponding elements in the original coefficients files. Default weights are read from the region-generic data file.

In most cases, AVERAGE uses the default weights to calculate the average input-output coefficients. Exceptions arise where coefficients in the original coefficients files have zero values assigned by EXTRACT using the TABLO zerodivide default facility. In such cases, the underlying input-output table contains no information about the coefficient, and we wish to assign the coefficient a zero weight.

The exceptional cases are handled as follows. Where just one of the original coefficients files contains a zero assigned by the zerodivide default facility, the new value is set equal to the value from the other original file. Where both the original files contain zeros assigned by the zerodivide default facility, the new value is set equal to zero.

To apply this treatment, AVERAGE must distinguish zero values assigned by the zerodivide default facility from zero values calculated as the quotient of a zero dividend by a non-zero divisor. The structure of the coefficients file and the design of EXTRACT allows it to do this. In the coefficients file generated by EXTRACT, each set of share coefficients with a common divisor normally sums to one. But if the divisor is equal to zero, EXTRACT applies the zerodivide default and sets the coefficients to zero. The coefficients then sum to zero. To determine which zero values are zeros assigned by the zerodivide default, AVERAGE calculates sums of coefficients with a common divisor. If the sum is equal to one, none of the coefficients has a zero value assigned by the zerodivide default; if the sum is zero, they all have.

PROJECT

PROJECT is a TABLO-written FORTRAN program designed to revise an input-output table, using a new input-output structure, but preserving the original indirect tax structure and final demand profile.

PROJECT reads a single-region input-output table, an input-output coefficients file, and the region-generic data file. It generates a new input-output table. We

use PROJECT to generate revised individual-region input-output tables with non-zero trade flows.

PROJECT is an implementation of an input-output model. Unlike most TABLO-implemented models, this model is expressed 'in the levels' rather than in change or percentage change form. This is possible because the model is intrinsically linear, rather than a linearisation of a non-linear model. The variables in the model represent input-output flows, and the equations in the model represent input-output accounting identities. The single-region input-output table, the coefficients file, and the region-generic data file provide the database for the model. The TABLO database update facility is used to generate the new input-output table.

As usual with TABLO-implemented models, the user is required to specify the solution procedure, closure and shocks for each simulation.

PROJECT calculates indirect tax rates and the aggregate components of final demand from the original input-output table. It uses these, together with the share coefficients from the input-output coefficients file, as coefficients in an equation system. The variables in the equation system include variables corresponding to all the flows in a SALTER single-region input-output table. Thus the solution of the system defines a new input-output table, which the program writes to an output file using the update facility.

Since the model implemented by PROJECT is linear, the user should always specify the linear (one-stage, single-step) solution procedure.

Besides variables representing input-output flows, PROJECT contains a dummy variable, named 'one'. In PROJECT simulations, the user should specify the variable 'one' as exogenous, and apply to it a shock of one. All other variables in the model should be specified as endogenous.

FIT

FIT is a TABLO-written FORTRAN program, designed to adjust an input-output table to external information about final demand, external trade, and the indirect tax structure.

FIT implements an augmented input-output model. It reads a single-region input-output table and the region-generic data file. Taking these as the initial database, it performs a simulation and uses the database update facility to write a new input-output table. The user is required to specify the solution procedure, closure and shocks for each simulation.

A detailed description of FIT is provided in James and McDougall (1993).

5 Procedure and implementation

The procedure for the later stage processing involves assembling the necessary data files and programs, preprocessing to remove zero trade flows, the FIT update simulations, and checking the updated input-output tables.

Later stage processing can be performed on microcomputers running under the Microsoft MS-DOS operating system.

Files used in the later stage processing include the programs described above, various utilities for checking the updated tables, a DOS batch file described below, initial single-region input-output tables from the first stage of database preparation, and miscellaneous data files including the region-generic data file described above and files containing data for the update targets.

For a single-region database to be valid it must satisfy certain sign and balance conditions. The sign conditions require various input-output flows to be non-negative. The balance conditions require equality between total costs and total sales of each industry.

For the later stage processing to be successful the initial input-output tables must satisfy the sign conditions. Checks on these conditions should therefore be included in the first stage of database preparation. We apply these checks using a utility called CHECKNEG. CHECKNEG is a TABLO-generated FORTRAN program (Brown *et al.* forthcoming)

While obviously desirable, it is not necessary for the later stage processing that the initial tables satisfy the balance conditions. This is because the preprocessing automatically eliminates any initial imbalances. Specifically, the program PROJECT always generates a balanced database. Indeed, PROJECT

can be used independently in conjunction with EXTRACT to balance an unbalanced input-output table.

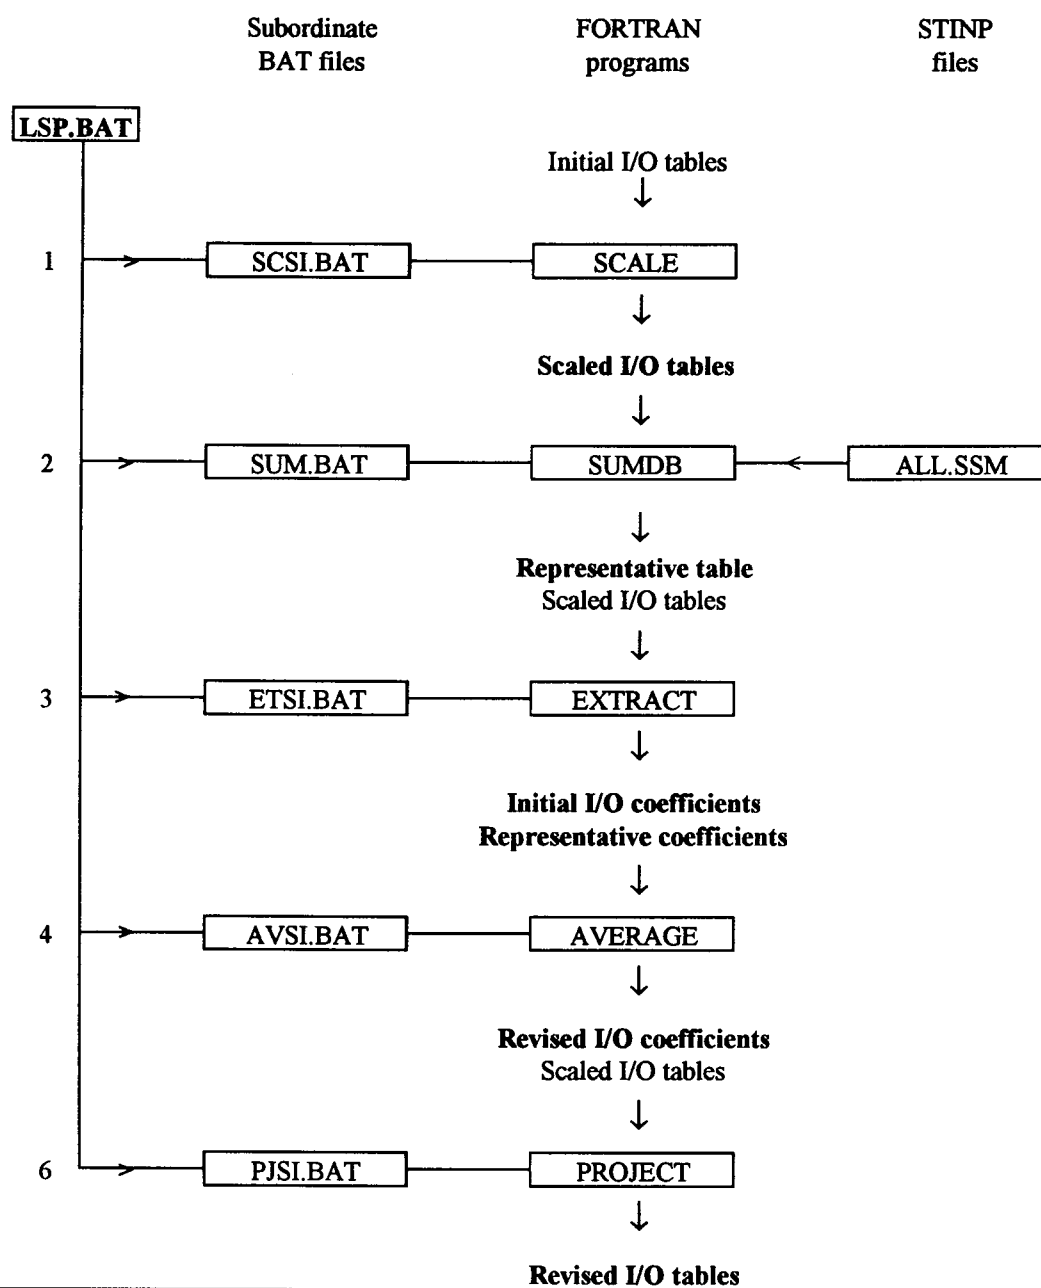

Thus the steps involved in the preprocessing are as follows:

- Using SCALE to rescale the initial input-output tables, applying target values for gdp in 1988, expressed in millions of US dollars.
- Using SUMDB to generate the representative input-output table by summing over the rescaled individual-region input-output tables.
- Using EXTRACT to generate input-output coefficients files from the individual-region input-output tables and the representative table.
- Using AVERAGE to revise the input-output coefficients for the individual regions, by averaging them with the coefficients from the representative table.
- Using PROJECT to revise the individual-region input-output tables, adjusting them to the revised input-output coefficients while preserving unaltered the final demand profile and indirect tax structure.

All these steps can be conducted with a single command by means of a batch file, LSP.BAT. The batch file contains information about file names, and target values for gdp for use with SCALE. It calls several subordinate batch files. The operations performed by the batch file are depicted in Figure 1.

Source code for the programs used in the later stage processing, and batch files for the preprocessing, are stored on diskette in a file LSP.ARC.

Appendix B: Source Code For Program SUMDB

```
PROGRAM SUMDB
C
C ACRONYM
C -----
C
C ADD several Header ARray files (cell by cell within an array)
C SUMDB
C
C
C DESCRIPTION
C -----
C
C This program allows a user to add the contents of several Header
C Array files containing 2-dimensional real, integer or character
C arrays, or 7-dimensional real arrays. The program adds cell by
C cell values within each real array and copies the other arrays,
C from the first file.
C
C
C CURRENT VERSION
C -----
C
C Version 1      January 1992

* MAXDIM, LNAME, FOUND,

* ERRMES)

C

C ACRONYM

C -----

C

C FIND the ARray specified.

C FIND AR

C

C DESCRIPTION

C -----

C

C This searches the Header Array file for the
C specified header.

C If it is found, it returns the data type of the array, its
C size and long name.

C The logical variable FOUND must be tested after a call to
C this to check whether the header was found on the file.

C

C CURRENT VERSION

C
C (1) SPECIFICATION:
C
C None is available at present.
C
C HISTORY
C -----
C
C Date      Author(s)      Comments
C -----
C 10 July 1986  Ken Pearson    Version 1.
C                      Initial coding
C
C 02 Sept 1992  A Strzelecki   Version 2.
C                      Read 7-D arrays
C
C NOTES
C -----
C
C - If the header HEADER is found on the file, on return
C   the file is positioned just before the record containing
C   HEADER.
C - If, on return, FOUND is .TRUE. then
C
C   -- if DTYPE is '2I' or '2R', NELS(1) and NELS(2) hold the
C   numbers of rows and columns of the matrix,
C   -- if DTYPE is '1C', NELS(1) is the number of strings and
C   NELS(2) is the length of each string.
C
C   -- if DTYPE is 'RL' NELS(.) hold the dimensions
C   of the matrix, and NUMDIM holds the number of dimensions.
C
C - If, on return, FOUND is .FALSE., all of DTYPE, NELS and NUMDIM
C   are undefined.
C

```

```

C
C SUBROUTINE VARIABLES
C -----
C
C (1) INPUT VARIABLES (NOT ALTERED):
C
C   UNIT   - The logical unit number of the Header Array file.
C   HEADER - The specified header.
C   MAXDIM - Maximum number of dimensions in Gempack header arrays
C
C   INTEGER    UNIT
C   CHARACTER*(*) HEADER
C
C (2) OUTPUT VARIABLES (RETURNED):
C
C   DTYPE - The data type.
C   NELS(.) - The dimensions array.
C   NUMDIM - The number of dimensions of the specified array.
C   LNAME  _ The long name associated with the array.
C   FOUND  - A logical variable, indicating whether or not the
C             header HEADER was found on the file.
C
C   CHARACTER*(*) DTYPE
C   INTEGER    NUMDIM, MAXDIM
C   INTEGER    NELS(MAXDIM)
C   CHARACTER*(*) LNAME
C   LOGICAL    FOUND
C
C (3) INPUT/OUTPUT VARIABLES:
C
C   ERRMES - Contains fatal error messages if ERRMES(1:1)='E'
C
C   CHARACTER*(*) ERRMES
C
C SIGNIFICANT PARAMETERS

```

```

C -----
C
C   SUBNAM - the name of this subroutine.
C   LLHEAD - the length of headers on a Header Array file.
C   FILPB  - the all-blanks character constant at the start of all
C             non-header records of a Header Array file.
C   LLSTM  - The length of character variables describing storage
C             method.
C   LLNAME - The length of long names on Header Array files.
C   MMSUM  - the maximum number of summary integers allowed on this
C             record (as presently implemented).
C
C   CHARACTER*6 SUBNAM
C   PARAMETER (SUBNAM='FINDAR')
C
C   INTEGER LLHEAD
C   PARAMETER( LLHEAD=4)
C   CHARACTER*(LLHEAD) FILPB
C   PARAMETER( FILPB='  ')
C
C   INTEGER LLSTM
C   PARAMETER( LLSTM=4)
C
C   INTEGER LLNAME
C   PARAMETER( LLNAME=70)
C
C   INTEGER MMSUM
C   PARAMETER( MMSUM=7)
C
C   SIGNIFICANT LOCAL DECLARATIONS
C -----
C
C   STMETH  - The storage method for the array.
C   SUM(MMSUM) - Array to hold the summary integers associated with
C             the header array in question.

```

C NSUM - The number of summary integers, as read from the file.

C

CHARACTER*(LLSTM) STMETH

INTEGER SUM(MMSUM)

INTEGER NSUM

C

C ERROR CHECKING AND HANDLING

C -----

C

C (1) VALIDATION OF SUBROUTINE INPUT VARIABLES:

C

C A fatal error (ERRMES(1:1)='E') results if:

C

C - HEADER contains only blanks.

C - LEN(HEADER) is different from LLHEAD.

C - MAXDIM is different from NSUM

C

C (2) VALIDATION OF DATA RETURNED FROM OTHER SUBROUTINES:

C

C A fatal error (ERRMES(1:1)='E') results if:

C

C - DTYPE or LNAME are variables of the wrong character lengths
C (subroutine RDR2HA).

C - DTYPE, STMETH, NSUM and SUM(1..NSUM) are incompatible with current
C implementation (subroutine RDR2HA).

C - There is a read error (subroutine RDR2HA).

C

C (3) VALIDATION OF SUBROUTINE OUTPUT VARIABLES:

C

C A fatal error (ERRMES(1:1)='E') results if:

C

C - NELS(1) is defined and is less than 0.

C - NELS(2) is defined and is less than 0 (real or integer data) or
C is less than 1 (character data).

C

```
